Abstract: Cloud computing has emerged as a platform that grants users with direct yet shared access to remote computing resources and services. Cloud must provide services to many users at the same time; the scheduling strategy should be developed for multiple tasks. In cloud computing processing is done on remote computer hence there are more chances of errors, due to the undetermined latency and loose control over computing node. Hence remote computers should be highly reliable. This is reason why a cloud computing infrastructure should be fault tolerant as well scheduling properly to performing tasks. This paper mainly deals with a fault tolerance model for cloud computing & Paper describes model for Fault Tolerance in Cloud computing (FTMC) FTMC model tolerates the faults on the basis of reliability of each computing node. A Computing node is selected for computation on the basis of its reliability and can be removed, if does not perform well for applications.

General Terms:

Cloud Computing, Fault Tolerance

Keywords:

Cloud Computing, Fault Tolerance, and Reliability

1. INTRODUCTION

Cloud computing is a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services). . Cloud computing emerges as a new computing paradigm which aims to provide reliable, customized and QoS (Quality of Service) guaranteed computing dynamic environments for end-users. Overall, cloud computing brings new aspects in computing resource management: infinite computing resources available on demand for the perspective of the end users; zero up-front commitment from the cloud users; and short-term usage of any high-end computing resources [11], [12].The basic principle of cloud computing is that user data is not stored locally but is stored in the data center of internet. The companies which provide cloud computing service could manage and maintain the operation of these data centers. The users can access the stored data at any time by using Application Programming Interface (API) provided by cloud providers through any terminal equipment connected to the internet. Not only are storage services provided but also hardware and software services are available to the general public and business markets. The services provided by service providers can be everything, from the infrastructure, platform or software resources. Each such service is respectively called Infrastructure as a Service (IaaS), Platform as a Service (PaaS) or Software as a Service (SaaS).To give services to end

users a cloud computing environment should be reliable & should manage to give output in minimum amount of time. Hence fault tolerance & task scheduling are the two important parameters for a system to be reliable. Cloud Computing environment should able to work on two basic characteristics that is Timeliness & Fault tolerance. By timeliness, we mean that each task in real time system has a time limit in which it has to finish its execution. And by fault tolerance means that it should continue to operate under fault presence.

2. RELATED WORK

Cloud computing is gaining an increasing popularity over traditional information processing systems for storing and processing huge data. This computing model is built on modern data centers made up of thousands of interconnected servers with capability of hosting a large number of applications.[8] Most often, these data centers are virtualized, and computing resources are provisioned to the user as an on demand services over the Internet in the form of configurable Virtual Machines (VMs) [9]. Cloud infrastructure should be fault tolerance. Lot of work has been done up till date to make cloud infrastructure fault tolerant. In cloud computing latency of node or virtual machine is unknown, as it always changes over a time.[2].User of a cloud do not know at exactly which node his request is being processed. but one advantage of a cloud computing is that it has capability to scale up dynamically. So that any node which is not working properly can be removed &also new node can be added

to get maximum output from cloud. X. Kong et. al. [1, 2] presented a model for virtual infrastructure performance and fault tolerance. But it is not well suited for the fault tolerance of real time cloud applications. A model for non-cloud environment is proposed by J. Coenen and J.Hooman [3] which describes a model for fault tolerance in distributed real time system. Ravi Jhavar, Vincenzo Piuri, Marco Santambrogio in their paper [4] “A Comprehensive Conceptual System-Level Approach to Fault Tolerance in Cloud Computing”, describes a framework for user in which user can specify and apply the desired level of fault tolerance without requiring any knowledge about its implementation with the help of dedicated user service layer. Another model is “time stamped fault tolerance of distributed RTS” [5], which is proposed by S. Malik and M. J. Rehman. This model proposed time stamping with the outputs. All these models mainly deals with the fault tolerance without taking reliability of computer nodes into consideration. Fault Tolerant system means system should work under the presence of fault.[4]. Techniques to build efficient and fault tolerant applications for Amazon’s EC2 are provided in [6]. Another approach using fault tolerance in middleware which follows a leader/follower replication approach to tolerate crash faults has been proposed in [7]. However, all these techniques either tolerate only a specific kind of fault or provide a single method to resilience. The reliability of cloud system is a major concern among users. In “Approach for constructing a modular Fault tolerant protocol” paper by M.Hiltunen & R.D. Schlichting proposed a modular protocols & combining them to a system using hierarchical techniques.[10].

2. FAULT TOLERANCE MODEL IN CLOUD COMPUTING (FTMC)

The given system deals with the fault tolerance mechanism. In this system, a model name fault tolerance model for cloud (FTMC) model is based upon reliability assessment of computing nodes known as a virtual machines (VM) in cloud environment and fault tolerance of real time applications running on those VMs. A virtual machine is selected for computation on the basis of its reliability and can be removed, if does not perform well for real time applications. In this scheme, ‘N’ virtual machine, which run the ‘N’ variant algorithms Algorithm ‘X1’ runs on ‘Virtual machine-1’, ‘X2’ a run on ‘Virtual machine-2’, up till ‘Xm’, which runs on ‘Virtual machine m’. Then there is ACCEPTER which is responsible for the verification of output result of each node. The outputs are then passed to TIMER which checks the timing of each result. On the basis of the timing the RELIABILITY ASSESSOR calculates and reassigns the reliability of each module. Then all the results are forwarded to DECISION MAKER which selects the output on the basis of best reliability. The output of a node with highest reliability is selected

2.1 Working of Model

In the fault tolerance mechanism, has M virtual machines. Each node is taking input data from the input

buffer. This input is concurrently passed to all the virtual machines. Each node takes the input, executes the application algorithm and produces result. These results are passed to ACCEPTER module. ACCEPTER module then passes these results to the assembly node for result decision and reliability assessment. The different modules in the system have the given responsibility. As we stated earlier that all the VMs are running different real time algorithms. These algorithms are different from each other by their implementation language, logics, software, operating systems etc.

ACCEPTER module is provided for each VMs. It performs testing on VMs for each iteration. Testing is carried out on algorithms running on each virtual machine. If a given algorithms gives desired result then it further passes to assembly nodes. If result is incorrect then it does not pass it to assembly nodes. Assembly nodes consist of TIMER module, RELIABILITY ASSESSOR (RA) module & DECISION MAKER (DM) module.

In **TIMER** module timer is set for each VM. It monitors the timing results produced by each VM. It receives the output of ACCEPTER module & passes only those correct results from a node which produces before time.

RELIABILITY ASSESSOR (RA) module assesses the reliability for each virtual machine. The reliability of the virtual machine changes after every computing cycle. At the start, the reliability of each virtual machine is 100%. If a processing VM manages to produce a correct result within the time limit, its reliability increases. And if the processing VM fails to produce the correct result or result within time, its reliability decreases. Every virtual machine has its predefined limit value for maximum & minimum reliability. If reliability of any processing VM falls below minimum reliability value then RA will restrict that node from working & removes it by sending a message to resource manager to remove it & add new node in place of that particular node. If reliability of all the nodes fall below minimum reliability level, the system either perform the backward recovery or stop the system to work further. The output of RA will then further passes to DM module.

DECISION MAKER (DM) module takes the input from RA module. It selects the output of the node which has highest reliability among all the competing nodes. Competing nodes are those nodes which have produced the results within There is a SRL (system reliability level). It is the minimum reliability level to be achieved to pass the result. DM compares the best reliability with the system reliability level. Best reliability level should be greater than or equal to time. system reliability level. If the node with best reliability does not achieve the SRL the DM raises the failure signal for the computing cycle. In this case, backward recovery is performed. Backward is performed by the help of check point established in recovery cache. DM

also request to some responsible module (resource manager or scheduler) to remove one node with minimum reliability and add a new node.

Check Point (CP) is the points from where backward error recovery is done in case of complete failure of a system. This scheme provides an automatic forward recovery. If a node fail to produce output or produce output after time overrun the system will not fail. It will continue to operate with remaining nodes. This mechanism will produce output until all the nodes fail.

2.2 Fault Tolerance Mechanism

Reliability assessment algorithm is applied on each node (virtual machine) one by one. Initially reliability of a node is set to 1. There is an adaptability factor n , which controls the of reliability assessment. The value of n is always greater than 0. The algorithm takes input of three factors RF , minReliability and maxReliability from configuration file. RF is a reliability factor which increases or decreases the reliability of the node. Min Reliability is the minimum reliability level. If a node reaches to this level, it is stopped to perform further operations. Max Reliability is the maximum reliability level. Node reliability cannot be more than this level. If there are two nodes and both of them have 10 passes and 10 failures in total 20 cycles. But the node who have more failures in near past has more chances to have lesser reliability than the other. This factor is really in accordance to latency issues, where initially node latency was good, but then it becomes high. So this node tends to more node failures by failing to produce the results in time. The values of variables (RF , minReliability , maxReliability , SRL) depend on the real time applications. User has to decide how much be the value for each variable.

Reliability Assessment Algorithm:

Start

Initialized reliability:=1, $n := 1$

Input RF , ma Reliability , min Reliability

Input processing node status

if processing node Status =Pass **then**

reliability: = reliability + (reliability * RF)

if $n > 1$ **then**

$n := n-1$;

else if processing node Status = Fail **then**

reliability: = reliability – (reliability * $RF * n$)

$n := n+1$;

if reliability \geq max Reliability **then**

Reliability: = max Reliability

if reliability $<$ min Reliability **then**

Processing node Status: =dead

Call Add new node ();

Stop.

Decision Maker Algorithm

Start

Initialized reliability: =1, $n := 1$.

input from RA processing node Reliability.

Input SRL.

Best Reliability: = find reliability of node with highest reliability.

if best Reliability \geq SRL

status: = success

else

status :=assign to input buffer.

Calls remove processing node min Reliability

Call add new processing node

Stop.

3. RESULTS & DISCUSSION

After applying FTMC algorithm, following results are found.

| Cycle | VM1 | Reliability | VM2 | Reliability |
|-------|------|-------------|------|-------------|
| 1 | Fail | 0.69 | Pass | 0.74 |
| 2 | Fail | 0.64 | Pass | 0.70 |
| 3 | Fail | 0.62 | Fail | 0.68 |
| 4 | Pass | 0.70 | Pass | 0.74 |
| 5 | Fail | 0.65 | Pass | 0.70 |

Table 3. Results after applying FTMC

From above table it can be seen that after 5 CPU cycle status of VM1 is fail at last cycle while status of VM2 is pass for last 2 cycles. Hence VM2 will be output of Decision maker module because it having less no failures in recent CPU cycle.

4. FUTURE SCOPE

We can further make cloud environment more faults tolerant by including more parameters in decision maker module.
